*Received 25 February 2004; revised 19 April 2004; accepted 16 May 2005*

The *dc* conductivity ( $\sigma$ ) and thermoelectric power (TEP) have been measured for the bulk binary alloy  $\text{Ge}_{40}\text{Te}_{60}$  and ternary alloy  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$ . X-ray diffraction confirms that the samples are polycrystalline. The measurements were carried out in the temperature range  $133 < T < 400$  K. Variation of electrical conductivity with ambient temperature ( $T$ ) proved the semiconductor behaviour for all range of  $T$  for both materials. With annealing time ( $t_{an}$ ), the electrical conduction activation energy ( $E_\sigma$ ) has been found to be with range from  $0.11 \times 10^{-3}$  eV- $63.3 \times 10^{-3}$  eV for  $\text{Ge}_{40}\text{Te}_{60}$  and from  $0.95 \times 10^{-3}$  to  $52.93 \times 10^{-3}$  eV while the thermo-electric power activation energy ( $E_s$ ) has been found to be in the range  $2.28 \times 10^{-3}$ - $39.3 \times 10^{-3}$  eV and  $1.58 \times 10^{-3}$ - $34.2 \times 10^{-3}$  eV for two alloys, respectively.

**Keywords:** Electrical conductivity, Thermo-electric power, Activation energy

### 1 Introduction

For several practical application reasons the IV-VI semiconducting compounds  $\text{A}^{\text{IV}}\text{B}^{\text{VI}}$  ( $\text{A}^{\text{IV}} = \text{Ge}, \text{Sn}, \text{Pb}$ ;  $\text{B}^{\text{VI}} = \text{S}, \text{Se}, \text{Te}$ ) have attained great interest and attention<sup>1-5</sup>. In addition, they also possess some unusual and possibly unique properties such as high dielectric constant and high carrier mobility as well as a narrow fundamental gap of several tenths of an electron volt at the  $L$  point. As a result of their narrow fundamental gap, the IV-VI semiconductors are suitable as infrared detectors and light emitting devices. Hence, their optical and electric properties both theoretically<sup>6-9</sup> and experimentally<sup>10-12</sup> have been studied.

Haruvi-Busnach *et al.*<sup>4</sup> have prepared chalcogenide glasses of the systems Ge-Sn-Se, Ge-Se-Te and Ge-Sn-Se-Te. They used X-ray diffraction, DSC (differential scanning calorimetry), SEM (scanning electron microscopy) with EDAX (energy dispersive analysis of X-ray) analysis, FTIR spectrometry to characterize the glasses. They found the glass transition temperature and microhardness of Ge-Sn-Se and Ge-Sn-Se-Te glasses decrease with increasing Sn content for most of the samples. The region of high IR transparency of Ge-Sn-Se, Ge-Se-Te and Ge-Sn-Se-Te glasses was slightly expanded (1-2  $\mu\text{m}$ ) towards longer wavelengths, compared to Ge-Se glasses, mainly for the glasses containing  $\leq 70$  % Se. The

intensity of the impurity absorption peak Ge-O (at  $\lambda \sim 12.8 \mu\text{m}$ ) which usually appears in Ge-Se glasses, was reduced or was absent in Ge-Sn-Se-Te glasses. The mechanical and optical characteristics of these glasses have been related to the glass structure.

Meaningful interpretation of the nature of electron transport is difficult without detailed *dc* conductivity studies. Thus, the effect of both the ambient temperature and the time of annealing on Seebeck coefficient and the electrical conductivity of  $\text{Ge}_{40}\text{Te}_{60}$  and  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$  alloys has been investigated.

### 2 Experimental Details

The two samples  $\text{Ge}_{40}\text{Te}_{60}$  and  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$  were prepared using the conventional melt-quench technique. Appropriate amount of high purity (99.99%) constituent elements were sealed in a quartz ampoule 8 mm diameter at about  $10^{-3}$  pa. Alloying was performed at  $900^\circ\text{C}$  for 12 h. During alloying the ampoule was shaken rigorously several times to ensure thorough mixing of the constituents, and hence good homogeneity of the produced alloy. After that, the alloy was allowed to cool to  $600^\circ\text{C}$  in 6 h, and further cooled to  $400^\circ\text{C}$  also through 6 h.

Quenching was performed in ice cooled water. Bulk samples with parallel and optically flat surfaces were prepared by sawing using an automatic cutting machine with diamond saw. Polishing was performed

mechanically by means of a controlled velocity rotating disc. The measurements of the *dc* electrical conductivity were carried out using a pressure contact sample holder. The opposite parallel surfaces of a sample were painted with silver paste as contact electrodes. A conventional series current circuit was used. The current was measured by means of Keithley 175 digital multimeter (DMM), while the potential difference was measured by means of Keithley 177 microvolt DMM. The sensitivity of measuring current and potential difference was  $1 \times 10^{-6}$  A and  $1 \times 10^{-6}$  V, respectively. A copper-constantan thermocouple junction was used for monitoring the temperature.

The thermoelectric power measurements were carried out using the simple two heaters method with graphite electrodes. The difference in temperature between the two opposite surfaces of the sample was  $3^\circ\text{C}$  during the whole measurements. The thermoelectric voltage was measured by means of Keithley 177 microvolt DMM. The X-ray diffractograms of the samples were studied using X-ray diffractometer type Philips (Holland) model PW 1710. The X-ray diffractograms shown in Figs 1 and 2, show that the prepared sample materials  $\text{Ge}_{40}\text{Te}_{60}$  and  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$  have polycrystalline structure. Figure 1 shows that the most intense peaks correspond to those of the original composition GeTe. In addition, the less intense peaks correspond to the elements Te and Ge. It was observed that the intensity of the most peaks increases by annealing. Further, the position of the especially most intense peak has been shifted towards higher diffraction angle with annealing.

Figure 2 shows that the most intense peaks correspond to the ternary composition GeSnTe. The

other less intense peaks correspond to the binary phases GeTe and SnTe. In addition, the peaks for the elements Ge, Sn and Te could also be identified. In case of  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$ , the intensity of the most intense peak decreases due to annealing while still position of these peaks has been shifted towards higher diffraction angle.

### 3 Results and Discussion

The two samples  $\text{Ge}_{40}\text{Te}_{60}$  and  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$  were annealed isothermally at  $200^\circ\text{C}$  for different times (0, 40, 160, 640, 1280 minutes). The *dc* conductivity  $\sigma$  and Seebeck coefficient (*S*) were measured after each period of annealing in the temperature range of  $133 < T < 400$  K. Figures 3 and 4 show the variation of  $\ln\sigma$  with  $1/T$  for  $\text{Ge}_{40}\text{Te}_{60}$  and  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$ , respectively. As shown in Figures 3 and 4, the plots corresponding to all periods of annealing at  $200^\circ\text{C}$  indicate two segments corresponding to two values of the activation energy. The temperature dependence is weak at lower temperatures confirming the domination of hopping conduction mechanism. Contrary to this, the temperature dependence becomes relatively stronger at higher temperatures which reveals the possibility of conduction due to extended state. Therefore, the temperature dependence of the electrical conductivity within this range can be described by the following usual Arrhenius equation

$$\sigma = \sigma_0 \exp\left(-\frac{E_\sigma}{kT}\right) \quad \dots (1)$$

where  $\sigma_0$  is the conductivity pre-exponential factor and  $E_\sigma$  is the activation energy for conduction. The

Fig. 4—Temperature dependence of conductivity at different annealing times for  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$ . The inset shows the dependence of conductivity on annealing time at  $T = 200^\circ\text{C}$

values of  $\sigma_0$  and  $E_\sigma$  were obtained by the least square fits of the experimental data of Figs 3 and 4, listed in Tables 1 and 2. In addition, the effect of the annealing time is also given in Tables 1 and 2. As it is seen in the inset in Figs 3 and 4, the annealing time dependence of  $\sigma$  at  $T = 200$  K shows N-like shape with maximum value of  $\sigma$  at the longest annealing time and minimum value for annealing time 0 min for the prepared samples of the two compositions. For the two composition the electrical conductivity activation energy increases with transition from one stage to the second successive higher stage of  $\sigma$ - $T$  dependence i.e.  $E_{\sigma 1} < E_{\sigma 2}$ . This indicates that the conductivity becomes more thermally activated with increasing temperature, this strengthens the prediction of dominance of hopping mechanism at the lower range of temperature.

Data in Tables 1 and 2 illustrate that for the Sn free composition, the values of both  $E_\sigma$  and  $\sigma_0$  are dependent on annealing time. Values of both  $E_{\sigma 1}$  (which corresponds to the relatively low range of  $T$ ) possessed minimum at 40 min while  $E_{\sigma 2}$  (which corresponds to the relatively high range of  $T$ ) showed unsequential change with prolongating time of annealing with its lowest value at 160 min of annealing. Meanwhile, the general trend was that,  $\sigma_{01}$  increased with increasing the annealing time, while  $\sigma_{02}$  changed unsequentially with prolongating the time of annealing.

For the second composition, the values of  $E_\sigma$  and  $\sigma_0$  fluctuate with prolongating the time of annealing as shown in Table 2.

As the prepared sample compositions have a polycrystalline structure indicated by XRD analysis (Figs 1 and 2), the conduction is expected to be mixed. In such a case, the measured conductivity is a sum of both extended ( $\sigma_{ext}$ ) and hopping ( $\sigma_{hop}$ ) components.

$$\sigma = \sigma_{ext} + \sigma_{hop} \quad \dots (2)$$

The plots in Figs 3 and 4 were extrapolated to the lowest temperature and then  $\sigma_{hop}$  was determined by subtracting the values of  $\sigma$  (low temperature) from the measured values of  $\sigma$ .

The Mott's formula<sup>13</sup> for the temperature dependence of the hopping conductivity is

$$\sigma_{hop} \sqrt{T} = \sigma'_0 \exp(-B/T^{1/4}) \quad \dots (3)$$

where  $B$  is given by<sup>14</sup>

$$B = T_0^{1/4} = 2.1 \left[ \frac{\alpha^3}{kN(E)} \right]^{1/4} \quad \dots (4)$$

where,  $\sigma'_0$  is a pre-exponent factor,  $\alpha$  describes the spatial extent of the localized wave function, which was assumed to be  $0.1 \text{ \AA}^{-1}$  and  $N(E)$  is the density of the localized states (DOLS) at the Fermi level.

| 1280                  | $3.41 \times 10^{-3}$ | 0.058                                | $19.50 \times 10^{-3}$ | 0.135                                | 243   |

The straight line fits shown in Figs 5 and 6 confirm that the conductivity data in the range below 260 K satisfy Mott's formula and can be used to calculate  $N(E)$  and consequently to calculate the basic parameters characterizing variable-range hopping (VRH) conduction namely<sup>13</sup>, the hopping distance( $R_h$ )

Fig. 5—The relation between  $\ln(\sigma T^{1/2})$  and  $T^{1/4}$  for  $\text{Ge}_{40}\text{Te}_{60}$  at different times of annealing

Fig. 6—The relation between  $\ln(\sigma T^{1/2})$  and  $T^{1/4}$  for  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$  at different times of annealing

and the hopping energy ( $W$ ) which are given, respectively, as

$$R_h = \left( \frac{9}{8\pi\alpha N(E)kT} \right)^{1/4} \quad \dots (5)$$

$$W = \frac{3}{4\pi R_h^3 N(E)} = \left( \frac{2\alpha^3 k^3 T^3}{9\pi N(E)} \right)^{1/4} \quad \dots (6)$$

The calculated values of  $N(E)$ ,  $R_h$  and  $W$  for the two compositions are listed in Table 3. The values of  $N(E)$  is the maximum at  $t_{an} = 40$  min for  $\text{Ge}_{40}\text{Te}_{60}$  and at  $t_{an} = 0$  min for  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$  and both  $R_h$  and  $W$  had a minimum at  $t_{an} = 40$  min for  $\text{Ge}_{40}\text{Te}_{60}$ .

For the  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$ ,  $N(E)$  attained a maximum before annealing, while both  $R_h$  and  $W$  have minimum values. Moreover, for the two considered compositions, the values of  $N(E)$  are unreasonably high compared to those recorded previously<sup>15,16</sup> for Ge alloys. This indicates that hopping may be the only dominant mechanism contributing to the conduction process in the compositions.

As it is seen in Figs 7 and 8 the plots between Seebeck coefficient ( $S$ ) and  $1/T$  in the same temperature range mentioned before for different

Fig. 8—The relation between Seebeck coefficient and  $1000/T$  for  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$  at different times of annealing

annealing times ( $t_{an} = 0, 40, 160, 640$  and  $1280$  min) are kinked linear. Accordingly, the temperature dependence of the differential thermoelectric power can be described by the following relation:

$$S = \pm \frac{k}{e} \left( \frac{E_s}{kT} + A' \right) \quad \dots (7)$$

where the plus and minus sign are for  $p$ -type and  $n$ -type materials, respectively.  $E_s$  represents the Fermi energy<sup>17,18</sup> (chemical potential).  $A'$  is a dimensionless parameter concerned with the carriers scattering mechanism<sup>19</sup> or assumed to be a measure of the kinetic energy transported by carriers<sup>20</sup>. The samples at all considered annealing times exhibited negative

sign TEP proving that these materials are of  $n$ -type. The electrons contributing to the observed TEP showed thermal activation and thus, the value of  $S$  increases continuously with increasing  $T$ . However, such thermal activation of electrons becomes more stronger as the temperature increase depends on the time of annealing. The relation between  $S$  and  $\frac{1}{T}$  can

be divided into two parts for all times of the two figures except for  $t_{an} = 640$  min and  $t_{an} = 40$  min for  $\text{Ge}_{40}\text{Te}_{60}$  and  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$ , respectively. At low range of temperature (first part), the contribution of holes to the observed thermoelectric power seemed very significant for  $t_{an} = 640$  min and  $t_{an} = 40$  min for  $\text{Ge}_{40}\text{Te}_{60}$  and  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$ , respectively, as almost entire compensation of the different sign contributing charge carriers could be observed at  $t_{an} = 640$  min and  $t_{an} = 40$  min, respectively.

Besides, values of the activation energy in the range below  $E_{s1}$  and above  $E_{s2}$ , the knee temperature ( $T_r$ ) and the dimensionless parameter  $A'_1$  and  $A'_2$  corresponding to the extrapolation of the ranges below and above  $T_r$ , vary with annealing time as shown in Tables 4 and 5.

As it is seen, the value of  $E_{s1}$  is in general small, this reflects the possibility of mixed conduction. Besides,  $E_{s1} < E_{s2}$ , which emphasizes that the contribution of electrons becomes more dominant in the relatively high range of temperature, the values of  $E_{s1}$  for  $t_{an} = 640$  min for  $\text{Ge}_{40}\text{Te}_{60}$  and  $t_{an} = 40$  min for  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$  are comparatively small with respect to those for other times of annealing indicating more significant contribution of holes at these times of

annealing. The corresponding relatively small values obtained for  $A'$  as seen in Tables 4 and 5 is a strong confirmation of mixed conduction behaviour.

Referring to the data in Tables 1-4, the variation of both  $E_\sigma$  and  $E_s$  with the time of annealing is similar.

This can be explained on the basis that addition of Sn has small effect on the internal microstructure. Furthermore, the unsequential variation in  $E_\sigma$  and  $E_s$  can reflect unsequential variation of the internal microstructure of both compositions with prolongating the time of annealing.

The difference between  $E_\sigma$  and  $E_s$  for two compositions confirms that hopping conduction can be dominant especially in the low temperature range.

#### 4 Conclusion

The X-ray diffractogram patterns showed that the method of preparation is successful for obtaining  $\text{Ge}_{40}\text{Te}_{60}$  and  $\text{Ge}_{38}\text{Sn}_2\text{Te}_{60}$  as dominant phases in the compositions. The  $\sigma$ - $T$  dependence emphasized the semiconductor behaviour of both compositions. Their electrical conduction is via the extended states in the higher range of temperature and is that of localized states in lower range of temperature. Moreover, the effect of the annealing time on  $E_\sigma$  may be controlled by two opposite (enhancing and inhibiting) factors. The  $S$ - $T$  relation showed that  $S$  has negative sign indicating that the two compositions are of  $n$ -type behaviour. The values of  $E_s$  determined for all considered annealing times ranged from  $\sim 1.5$  to 40 meV.
